WHAT MAKES FOR A HIT POP SONG?

NICHOLAS BORG AND GEORGE HOKKANEN

Overview

The possibility of a hit song prediction algorithm is both academically interesting and industry motivated. While several companies currently attest to their ability to make such predictions, publicly available research (most notably Pachet, [1]) suggests that current methods are unlikely to produce accurate predictions. We are currently investigating to what extent features extracted from the music itself can be used to classify popular music. Our own attempts to predict song popularity as measured by youtube views seem as unpromising as the results of Pachet. In order to address this question properly, we believe that we must also investigate the social factors that dictate music popularity. Given the lack of success of this feature/popularity correlation, we will be motivated after the milestone to attempt classifications of popularity with billboard charts, youtube views, and twitter hype, but this is a consideration for the future.

Dataset

Our analyses to date have been centered around the million song dataset subset which consists of ten thousand songs with metadata, chroma, and mfcc-like coefficients. The dataset is distributed by Labrosa for free usage [3]. One of the features given in the dataset is a popularity value called 'hotttnesss' produced by the Echonest, but this value appears too sparse in the data to be useful. For a popularity replacement measure, we have created a dataset of youtube view counts (coordinated with the subset only at the moment), ratings, and average rating of the first result for each query of artist name, song name. We checked by hand the accuracy of this scraping method and concluded that the two errors in thirty randomly drawn songs was not a problem given that the errors also coordinate well with very low view counts (i.e. something unpopular enough to not return a copy of the song on youtube ends up returning an unrelated video with a low view count).

Preliminary Analysis

In order to familiarize ourselves with the data, we first ran basic correlation coefficients between different parts of the metadata and also with our extracted youtube view counts. The results were largely insignificant and included weak correlations such as one of .2 between the tempo and loudness metadata features. Correlations between the youtube view counts and the echonest metadata features loudness, tempo, hotttness, and danceability were completely negligible (less than .05 in magnitude). The fact that these are not at all correlated is interesting in its own right because it points to no single metadata feature being at all a good predictor

of views on youtube.

We then made a shot in the dark, taking some number of mfcc's (usually less than 100) and concatenating them into a vector of length less than 1200. We trained an SVM using these vectors to predict the youtube view counts obtained through scraping, using several different kernels all to no avail (the accuracy was always less than .55). Intuitively, mfcc's provide a rather detailed description of a song over time. One way to account for the poor performance of our SVMs is by noting that treating the mfcc's as a vector of unordered features fails to account for the temporal progression of a song. For this reason, we hypothesized that a more intelligent implementation of an SVM trained on mfccs would use a string kernel, providing our classifier with a symbolic representation of the song over time. Our efforts in this direction are outlined in the following sections on Feature Extraction and Classification.

Feature Extraction

Given that the mfcc and spectral data is temporal, we wanted to use the ordering therein to describe the sound. Motivating a string kernel SVM approach, we create 'string' features for our songs as follows.

For each i, we take the spectral bucket i (corresponding to a frequency-aggregate magnitude) for each spectra vector within a range of each song (usually about 45 seconds in the middle). This gives a list of values which correspond to the magnitudes over time of this slice of the sound spectrum for every song.

Next, using a subset of this data (we used two hundred of the ten thousand songs) we compute a list of intervals (we used 26 of them, corresponding to the characters a through z) that uniformly distribute the data. Then using these intervals, we compute a string for each sequence of data obtained in the first step by replacing each value with a symbol or letter that represents the interval.

Classification

We used the string kernel SVM extension to libsvm with the strings obtained via the feature extraction method above with binary labels of youtube view counts being greater than or less than 100,000 and also multiclass using finer grained quantization of views, but found that it was unable to converge.

We hypothesize that the algorithm was unable to converge because our string kernel is currently using a string edit distance metric between strings of length 200 that are almost entirely unrelated in their exact symbolism, which produces very noisy data. Measures that we expect might work better involve taking two strings and then permuting all of the letters in the second and calculating the edit distance, then taking the smallest value. This, however, would be very

computationally intensive and potentially infeasible. Nonetheless, the motivation for such a metric stems from the idea that exact data is not very useful for the type of symbolic similarity we would like to calculate (the same logic which motivated us to use the quantized strings in the feature extraction above to begin with), and we plan on moving forward by investigating more general pattern matching (e.g. maximal subsequence similarity in our strings) to attempt to better understand what might be heard as similar sounding music.

Results and What's Next

Currently we have no good predictors (in fact, nothing above .55 accuracy) for song popularity as estimated by youtube views by using features extracted from spectral and MFCC coefficients, nor for the metadata given in the labrosa dataset. We expect that this is likely either a result of the musical features we are using not being descriptive of any popularity measure (something Pachet concludes in [1]), or that the social and cultural factors that dictate what songs become popular is chaotic enough that it is impossible to describe solely in terms of the musical content. In moving forward, we intend to attempt more feature extraction and calculate measurements such as the variance in the strings we have computed and possibly using Markov models to describe transition probabilities and extracting features from those. We also plan to mine Billboard top 100 charts and twitter (searching for artists and songs) to examine the relationships between song popularity as purely judged by the community of users consuming media on the web (youtube and twitter) and the official rankings of songs by record sales and airplay (Billboard). This analysis may demonstrate the occurrence of preferential attachment, whereby the popular artists retain more view counts simply by their having become popular.
